Linear pricing

Theorem. (Linear Pricing) Suppose there is no arbitrage. Suppose also

- Price of cash flow \mathbf{c}_A is p_A
- ullet Price of cash flow ${f c}_B$ is p_B

Then the price of cash flow that pays $\mathbf{c} = \mathbf{c}_A + \mathbf{c}_B$ must be $p_A + p_B$.

Let p denote the price of the total cash flow \mathbf{c} . Suppose $p < p_A + p_B$, i.e. \mathbf{c} is cheap! Will create an arbitrage portfolio, i.e. a free-lunch portfolio.

- Purchase c at price p
- Sell cash flow \mathbf{c}_A and \mathbf{c}_B separately

Price of the portfolio $= p - p_A - p_B < 0$, i.e. net income at time t = 0. The cash flows cancel out at all times. Future cash flows = zero. Free lunch!

No arbitrage \equiv no free lunch. Therefore, $p \geq p_A + p_B$

We can reverse the argument if $p > p_A + p_B$

• Note that we need a liquid market for buying/selling all the cash flows.

2

Simple example of linear pricing

Cash flow $\mathbf{c} = (c_1, \dots, c_T)$ is a portfolio of T separate cash flows

• $\mathbf{c}^{(t)}$ pays c_t at time t and zero otherwise.

Suppose the cash flows are annual and the annual interest rate is $\it r.$

Price of cash flow $\mathbf{c}^{(t)} = \frac{c_t}{(1+r)^t}$.

Price of cash flow $\mathbf{c} = \sum_{t=1}^{T}$ Price of cash flow $\mathbf{c}^{(t)} = \sum_{t=1}^{T} \frac{c_t}{(1+r)^t}$

3

Floating interest rates

Interest rates are random quantities ... they fluctuate with time.

Let r_k denote the per period interest rate over period [k, k+1)

- The exact value of r_k becomes known only at time k
- ullet 1-period loans issued in period k to be repaid in period k+1 are charged r_k

Cash flow of floating rate bond

- coupon payment at time k: $r_{k-1}F$
- ullet face value at time n: F

Goal: Compute the arbitrage-free price P_f of the floating rate bond

Split up the cash flows of floating rate bond into simpler cash flows

- $p_k = \text{Price of contract paying } r_{k-1}F$ at time k
- $P = \text{Price of Principal } F \text{ at time } n = \frac{F}{(1+r)^n}$

Price of floating rate bond $P_f = P + \sum_{k=1}^n p_k$

Price of contract that pays $r_{k-1}F$ at time k

Goal: Construct a portfolio that has a deterministic cash flow

ullet The price of a deterministic cash flow at time t=0 is given by the NPV

	t = 0	t = k - 1	t = k
Buy contract	$-p_k$		$r_{k-1}F$
Borrow α over $[0,k-1]$	α	$-\alpha(1+r_0)^{k-1}$	
Borrow $\alpha(1+r_0)^{k-1}$ over $[k-1,k]$		$\alpha(1+r_0)^{k-1}$	$-\alpha(1+r_0)^{k-1}(1+r_{k-1})$
Lend α from $[0,k]$	$-\alpha$		$ \begin{array}{l} r_{k-1}F \\ -\alpha(1+r_0)^{k-1}(1+r_{k-1}) \\ \alpha(1+r_0)^k \end{array} $

Cash flow at time k

$$c_{k} = r_{k-1}F - \alpha(1+r_{0})^{k-1}(1+r_{k-1}) + \alpha(1+r_{0})^{k}$$

$$= \underbrace{\left(F - \alpha(1+r_{0})^{k-1}\right)r_{k-1}}_{\text{random}} + \underbrace{\alpha r_{0}(1+r_{0})^{k-1}}_{\text{deterministic}}$$

Set $\alpha = \frac{F}{(1+r_0)^{(k-1)}}$. Then the random term is 0.

Net cash flow is now deterministic ... $c_k = \alpha r_0 (1+r_0)^{k-1} = \mathit{Fr}_0$

Price of floating rate bond (contd)

Price of the portfolio $= p_k - \alpha + \alpha = p_k = \frac{c_k}{(1+r)^k} = \frac{Fr_0}{(1+r)^k}$

Recall that

$$P_{f} = \frac{F}{(1+r_{0})^{n}} + \sum_{k=1}^{n} p_{k}$$

$$= \frac{F}{(1+r_{0})^{n}} + \sum_{k=1}^{n} \frac{Fr_{0}}{(1+r_{0})^{k}}$$

$$= \frac{F}{(1+r_{0})^{n}} + \frac{Fr_{0}}{(1+r_{0})} \sum_{k=1}^{n} \frac{1}{(1+r_{0})^{k-1}}$$

$$= \frac{F}{(1+r_{0})^{n}} + \frac{Fr_{0}}{(1+r_{0})} \cdot \frac{1 - \frac{1}{(1+r_{0})^{n}}}{1 - \frac{1}{1+r_{0}}}$$

$$= F$$

The price P_f of a floating rate bond is equal to its face value F

Term structure of interest rates

Interest rates depend on the term or duration of the loan. Why?

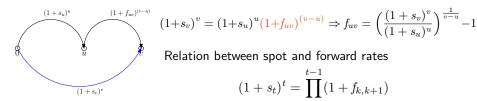

- Investors prefer their funds to be liquid rather than tied up.
- Investors have to be offered a higher rate to lock in funds for a longer period.
- Other explanations: expectation of future rates, market segmentation.

Spot rates: s_t = interest rate for a loan maturing in t years

$$A \text{ in year } t \implies PV = \frac{A}{(1+s_t)^t}$$

Discount rate $d(0,t) = \frac{1}{(1+s_t)^t}$. Can infer the spot rates from bond prices.

Forward rate f_{uv} : interest rate quoted today for lending from year u to v.

Relation between spot and forward rates

$$(1+s_t)^t = \prod_{k=0}^{t-1} (1+f_{k,k+1})$$
